On believing and hoping whether

Aaron Steven White
University of Rochester

Abstract  Theories of clause selection that aim to explain the distribution of interrogative and declarative complement clauses often take as a starting point that predicates like think, believe, hope, and fear are incompatible with interrogative complements. After discussing experimental evidence against the generalizations on which these theories rest, I give corpus evidence that even the core data are faulty: think, believe, hope, and fear are in fact compatible with interrogative complements, suggesting that any theory predicting that they should not be must be jettisoned.

Keywords: clause embedding, selection, interrogative, veridical, neg-raising, preferential

1 Introduction

* I am grateful to Judith Tonhauser as well as two anonymous reviewers for their extensive comments on this paper. I am also grateful to Kyle Rawlins for discussion of the work presented in Section 3.1; to Hannah An for discussion of the work presented in Section 3.2; and to Will Gantt and Ben Kane for general discussion of the paper. All of the data and code used for this paper can be found at megaattitude.io. This work was supported by National Science Foundation grant BCS-1748969 The MegaAttitude Project: Investigating selection and polysemy at the scale of the lexicon.

Following Grimshaw 1979, a canonical contrast in this literature is that between predicates like think, believe, hope, and fear — which are often judged worse with interrogative complements than with declaratives (1a) out of context — and know — which is often judged fine with both (1b).

(1)  
   a. Jo {thinks, believes, hopes, fears} (*whether) Bo left.  
   b. Jo knows (whether) Bo left.

This contrast is often taken to imply that know is compatible with both declarative and interrogative complements — i.e. know is a responsive predicate (Lahiri 2002) — while think, believe, hope, and fear are compatible with only declarative complements — i.e. they are antirogative predicates. This inference forms the basis for various generalizations that authors then attempt to derive. I discuss three influential proposals in Section 2.

The aim of this paper is to show that, not only are these generalizations (and thus their derivations) nonviable when evaluated across a broad swath of the English verb lexicon; even the inference from the contrast in (1) to the antirogativity of think, believe, hope, and fear is unlicensed based on an assessment of the broader empirical landscape. And, I argue, because these predicates’ (purported) antirogativity forms the core data for all of these generalizations, the generalizations are left so frail without these data that they should be jettisoned altogether.

I first review prior experimental evidence against one of these proposals in Section 3 and then present further evidence against a second based on existing datasets. This evidence leaves open the possibility that the proposed generalizations might be saved by further constraining them. Using corpus examples drawn from a variety of genres, I suggest in Section 4 that any such constrained version must jettison the contrast in (1) as supporting evidence.

2 Proposed generalizations

Egré (2008) proposes generalization V.

V A predicate is responsive iff it is veridical.

WHERE a predicate v is *veridical* in a sentence NP V S iff one infers from NP V S that s.1

1 Interpreting *predicate as predicate type* and *sentence as sentence type*, this definition of veridicality is consistent with a more common definition: that a predicate v is *veridical* iff NP V S entails s. For reasons discussed below, I avoid a definition in terms of entailment, which would imply a property of all possible uses of sentences containing a token of some predicate type.
On believing and hoping whether

*Think* and *believe* are not veridical — from (2a), one does not infer that (3) — and so they should not be responsive according to *V*. In contrast, *know* is veridical — from (2b), one infers that (3) — and so it should be responsive according to *V*.

(2)   a. Jo {thinks, believes} Bo left.
    b. Jo knows Bo left.

(3)   Bo left.

Thus, insofar as the inference is licensed from the contrast in (1) to the responsivity of *know* and the antirogativity of *think*, *believe*, *hope*, and *fear*, the predictions of *V* are correct for those predicates.

Theiler, Roelofsen & Aloni (2017, 2019), following Zuber (1982), propose generalization NR with similar consequences.

NR  A predicate is antirogative if it is neg-raising.

    WHERE a predicate *v* is *neg(ation)-raising* in sentence *NP not v s* if one can infer from *NP not v s* that *NP v not s*

*Think* and *believe* are also neg-raising — from (4a), one can infer (4b) — and so they should not take interrogatives according to NR.

(4)   a. Jo doesn't {think, believe} Bo left.
    b. Jo {thinks, believes} Bo didn't leave.

Importantly, since NR takes the form of a conditional — rather than a biconditional, like *V* — it predicts nothing about the distributional properties of non-neg-raising predicates. Thus, insofar as the inference is licensed from the contrast in (1) to the antirogativity of *think* and *believe*, the predictions of NR are correct for those predicates. This outcome is positive for NR: *hope* and *fear* are standardly assumed to be non-neg-raising (see Uegaki & Sudo 2019), but if NR took the form of a biconditional, it would predict *hope* and *fear* to be responsive, thereby conflicting with the inference from the contrast in (1) to the antirogativity of *hope* and *fear*.

In an attempt to extend Theiler, Roelofsen & Aloni’s proposal to predicates like *hope* and *fear*, Uegaki & Sudo (2019) propose generalization *V + P*.

*V + P* A predicate is antirogative if it is nonveridical and preferential

    WHERE a predicate *v* is *preferential* iff focus in the scope of the predicate has a truth conditional effect.
Hope and fear are not veridical—from (5), one does not infer (3)—but they are preferential (see Uegaki & Sudo’s Ex. 11), and so they should not take interrogative complements according to $V + P$.

(5) Jo {hopes, fears} Bo left.

Like NR, $V + P$ takes the form of a conditional: it predicts nothing about the distributional properties of veridical predicates, like know, or nonpreferential predicates, like think and believe.

In what follows, I assume what I take to be the most charitable possible interpretation of each generalization: that each concerns inferences drawn on particular uses of any particular sense of a predicate that falls under the generalization. This interpretation is strictly weaker than the one commonly assigned to generalizations of this form—wherein (i) predicate and sentence in the definitions of $V$, NR, and $V + P$ are interpreted as predicate type and sentence type, respectively; and (ii) predicate types are associated with an inferential property, such as veridicality or neg-raising, if all relevant uses of the predicate in sentences of the relevant type have the property. This approach is useful, not only because counterexamples to the weak interpretation are always counterexamples to the more common (strong) interpretation (but not vice versa), but also because it can be hard to pin down whether the strong version of the generalization given in a particular paper is intended in the first place. This shows up in two contexts.

First, it is not always clear how to interpret lexical generalizations when a predicate has potentially multiple senses. Generally, predicate sense is invoked to save a generalization. For instance, at least Egré explicitly argues that tell has two distinct senses—one veridical and one nonveridical—and that only the veridical sense is responsive (see also Spector & Egré 2015). In contrast, other arguments rely on senses remaining constant. For instance, say with an infinitival complement is nonveridical and preferential under Uegaki & Sudo’s criterion yet responsive, counter to the predictions of $V + P$. To save $V + P$, Uegaki & Sudo are forced to stipulate that say only has a single nonpreferential sense—presumably, the same one that shows up with finite complements—and that that preferentiality comes from the infinitival complement. In light of these strategies, it seems reasonable to interpret

---

2 I call this move a stipulation because it requires unmotivated predicate-specific carve-outs: if the infinitival complement gives rise to preferentiality, it is unclear why decide with an infinitival complement should not be similarly preferential under Uegaki & Sudo’s definition—especially following current proposals about the classification of infinitives (Wurm-
On believing and hoping whether these generalizations as specific to whatever senses fall under them, rather than assuming that the generalization holds of a predicate if any sense of that predicate falls under it — even one that is plausibly related via a rule of regular polysemy.

Second, because at least neg-raising inferences are defeasible, a predicate sense might fall under a generalization, such as \( \text{NR} \), only in contexts where it is triggered. This interpretation is explicitly invoked by Theiler, Roelofsen & Aloni to save their generalization in the face of examples like (6), wherein \textit{believe} — a predicate that can trigger neg-raising inferences — appears to be compatible with an interrogative complement.

(6) You won’t believe who called (*in ages)!

They argue (their Footnote 11) that this compatibility is only possible when the neg-raising inference is not triggered. Evidence for the lack of a neg-raising inference in (6) comes from the fact that strong negative polarity items (strong NPIs; Zwarts 1998), like \textit{in ages}, cannot occur in the complement (Gajewski 2007). For this move to work, it must be that particular uses of a predicate (sense) in some context are relevant to \( \text{NR} \) — not the fact that the predicate can trigger the relevant inferences in some contexts. Thus, the weak interpretation of at least \( \text{NR} \) seems required. Absent an argument that (6) contains a veridical sense of \textit{believe}, such a move would similarly be required to save \( \text{V} \), for which (6) is a counterexample.

3 Experimental evidence against the generalizations

Under the interpretation of \( \text{V} \), \( \text{NR} \), and \( \text{V} + \text{P} \) just discussed, the explanation for the contrast in (1) must be that the default contexts against which the default senses of \textit{think}, \textit{believe}, \textit{hope}, and \textit{fear} are judged imply antirogativity. Assuming that, for a particular sentence, these default senses and contexts remain constant across acceptability and inference judgments, all three generalizations are testable given quantitative measures of veridicality, neg-raising, responsivity, and preferentiality.

Large-scale datasets from which such measures can be derived currently exist for veridicality (the \textit{MegaVeridicality dataset}; White & Rawlins 2018b), neg-raising (the \textit{MegaNegRaising dataset}; An & White 2020), and responsivity (brand 2014). But if the definition of preferentiality were modified to include \textit{decide}, it would create a counterexample to \( \text{V} + \text{P} \), since \textit{decide} is nonveridical but responsive.
ity (the MegaAcceptability dataset; White & Rawlins 2016, 2020)—enabling tests of V and NR—but to my knowledge, a sufficiently large-scale datasets measuring preferentiality does not yet exist. As such, I focus only on V and NR in this section. I first discuss existing quantitative evidence against V in Section 3.1. I then turn to a new analysis that provides evidence against NR in Section 3.2. Because all three measures are continuous in nature, I begin each subsection by using statistical simulations to cash out the relevant generalization’s quantitative predictions under different distributional assumptions and then compare the results of these simulations against the observed data.

3.1 Evidence against V

V predicts that one should find a perfect positive correlation across predicates (modulo measurement error) between measures of veridicality and responsivity. This prediction is visualized in Figure 1 (left), with points and correlations based on a simulation assuming 500 predicates. This simulation assumes (i) that each licit category (nonveridical antirogative and veridical responsive) is distributed multivariate normal and contains an equal number of predicates; (ii) that the variance for each dimension is equal within and across categories; (iii) that there are no correlations among dimensions within a category; and (iv) that the classes are extremely clearly delineated—in Figure 1 (left), the distance between the class centroids is 10 times the intraclass standard deviation along each dimension.

To give a sense for how sensitive the correlation is to these assumptions, Figure 2 (left) plots the simulated correlation when varying the proportion of veridical predicates and how distinguishable the categories are: the larger the ratio of distance between the category centroids to category standard deviation, the more distinguishable the categories. The main take-away from this plot is that, even in the worst case scenario where the categories are very hard to distinguish—i.e. the distance-standard deviation ratio is 0.5—the average correlation is around zero, with the lower bound of the confidence

---

3 The 0.1 line in Figure 2 (left) is overplotted by the 0.9 line, and the 0.3 line is overplotted by the 0.7 line. This pattern occurs because, for V, assuming a higher proportion of nonveridical antirogatives—i.e. putting more points in the lower left quadrant—has the same effect on correlation as assuming a higher proportion of veridical responsives—i.e. putting more points in the upper right quadrant. The same is not true for the simulations reported in Section 3.2.
interval never dipping below $-0.08$. That is, even if the measures of veridicality and responsivity are exceedingly noisy, it would be extremely unlikely to see a correlation more negative than $-0.08$ if V were true.

White & Rawlins (2018b) test the predictions of V, alongside the predictions of a closely related generalization that Egré attributes to Hintikka 1975 (see also Berman 1991, Ginzburg 1995). The fact that they simultaneously test both generalizations requires additional complexity in how they report their analysis that is not relevant here, and so I focus only on a replication of their analysis that assesses the correlation between their measures of veridicality and responsivity.

Using a veridicality judgment task to construct their MegaVeridicality dataset, White & Rawlins (2018b) obtain a quantitative measure of veridicality for a broad swath of English verbs that are acceptable with declarative complements — operationalized as an average acceptability judgment of 4 out of 7 or better for (7a) or (7b) in White & Rawlins’s (2016, 2020) MegaAcceptability dataset. A total of 517 verbs in MegaAcceptability fit this criterion.\footnote{White et al. (2018) substantially expand MegaVeridicality to predicates that take various types of infinitival complement. Since Egré discusses only finite interrogatives, I do not discuss this expansion.}

\begin{align*}
(7) & \quad a. \text{ Someone \{thought, knew, ...\} that something happened.} \\
    & \quad b. \text{ Someone was \{told, worried, ...\} that something happened.}
\end{align*}
White & Rawlins’ (2018) veridicality judgment task prompt is exemplified in (8) for know.\(^5\)

(8) Someone knew that a particular thing happened.
    Did that thing happen? yes, maybe or maybe not, no

To obtain a measure of each predicate’s veridicality from responses to prompts such as (8), White & Rawlins (2018b) apply an ordinal mixed model-based normalization procedure like that used by White & Rawlins (2020). This procedure, which produces more positive values for predicates that receive more yes responses and more negative values for predicates the receive more no responses, adjusts for biases in how particular participants use the ordinal scale and shows high correlation with mean by-participant \(z\)-scores (see White & Rawlins 2020: Appendix C).

White & Rawlins (2018b) then derive a measure of responsivity for each verb from MegaAcceptability using the normalized acceptability scores described by White & Rawlins (2016). They first derive a measure of interrogative-taking by taking the maximum average acceptability over both polar (9a) and constituent (9b) interrogatives. The idea behind this measure is to treat a predicate as interrogative-taking insofar as it is good with either polar or constituent interrogatives.\(^6\)

(9) a. Someone (was) {thought, told ...} whether something happened.
    b. Someone (was) {thought, told, ...} which thing happened.

They derive an analogous measure of declarative-taking by taking the maximum acceptability over both the overt (10a) and covert (10b) complementizer variants.

(10) a. Someone (was) {thought, told ...} that something happened.
    b. Someone (was) {thought, told ...} something happened.

Finally, to derive the measure of responsivity, they take the minimum of interrogative- and declarative-taking measures for each predicate. The idea behind this responsivity measure is to treat a predicate as responsive only

\(^5\) Their task manipulates the matrix polarity, but only the positive polarity items, such as (8), are relevant here, given the definition of veridicality in \(V\).

\(^6\) It is important to include constituent interrogatives in order to capture many emotive predicates, since these predicates are known to be degraded with polar interrogative complements (cf. Sæbø 2007).
On believing and hoping whether

Figure 2  Correlations under different simulation assumptions for V (left) and NR (right). Error bars shows 95% confidence intervals.

to the extent that it is good with both interrogatives and declaratives: to the extent it is degraded with either, taking the minimum sets the responsivity measure to the less acceptable of the two.

One thing this measure of responsivity does not account for is that it is sensitive to variability in the measure of declarative-taking, since White & Rawlins’ (2018) method for selecting predicates based on acceptability with declaratives allows predicates that might be quite middling with declaratives. This situation is potentially problematic because the generalizations discussed in Section 2 presuppose that a predicate is acceptable with declaratives; but it is largely unavoidable, since there is no natural acceptability threshold distinguishing grammatical and ungrammatical items in MegaAcceptability (see the histograms in White & Rawlins 2020: Appendix C). To deal with this, White & Rawlins (2018b) weight their analyses by acceptability with a declarative — predicates that are less acceptable with declaratives receiving less weight. To derive this weight, they $z$-score the measure of declarative-taking across only predicates in the MegaVeridicality and then apply the normal cumulative distribution function to those values. This method ensures that predicates that are the “most” declarative-taking have weights near 1 and that predicates that are the “least” declarative-taking have weights near 0.

Figure 3 (left) plots the measure of responsivity against the measure of veridicality, with transparency corresponding to the declarative-taking weight. The line shows a linear regression weighted by declarative-taking weight.
weight. The corresponding correlation weighted by declarative-taking is $-0.10$ (95% CI = $[-0.20, 0.00]$). This correlation violates the predictions of $\text{V}$, even under the worst-case simulation assumptions discussed above, suggesting that $\text{V}$ is false as a generalization about the lexicon as a whole.

### 3.2 Evidence against $\text{NR}$

$\text{NR}$ predicts a negative correlation between measures of neg-raising and responsivity. But in contrast to $\text{V}$, which takes the form of a biconditional, $\text{NR}$ does not predict that the correlation is perfect, since it takes the form of a conditional. The reason for this is visualized in Figure 1 (right), which employs similar distributional assumptions to Figure 1 (left). The predicted correlation is highly dependent on the ratio of the responsives to antirogatives among the non-neg-raisers. In Figure 1 (right), a ratio of 1 is assumed, and insofar as the ratio is high, the correlation will be higher and vice versa. Indeed, a correlation of 0 is technically compatible with $\text{NR}$ — the case where there are either no responsives or no neg-raisers — but it would leave $\text{NR}$ with effectively no predictive power.

To give a sense for how sensitive the correlation is to these assumptions, Figure 2 (right) plots the simulated correlation when varying the proportion

---

**Figure 3** Correlations between veridicality (left), neg-raising (right), and responsivity.
On believing and hoping whether

of neg-raising predicates and how distinguishable the categories are. For the
\( x \)-axis, the distance between the centroid of the non-neg-raising responsives
and the centroid of the neg-raising antirogatives is used to compute the ratio.
These plots do not vary the ratio of responsives to antirogatives among the
non-neg-raisers, leaving that ratio constant at 1. Analogous to the left plot,
the main take-away from this plot is that, even in the worst case scenario
where the categories are very hard to distinguish — e.g. where the distance-
standard deviation ratio is 0.5 — the correlation is around zero with the up-
per bound of the confidence interval never rising above 0.09. That is, even if
the measures of neg-raising and responsivity are exceedingly noisy, it would
be extremely unlikely to see a correlation more positive than 0.09 if NR were
true.

To test \( NR \), I deploy White & Rawlins' (2018) methodology in conjunc-
tion with An & White's (2020) MegaNegRaising dataset. An & White derive
a measure of neg-raising using a likelihood judgment task, wherein partici-
pants are asked to judge how likely a speaker is to mean one thing if they say
another. For instance, to assess whether \textit{think} is neg-raising in the present
tense with a first person subject, participants were asked to respond to (11)
with a slider.

(11) If I were to say \textit{I don't think that a particular thing happened}, how
likely is it that I actually mean that \textit{I think that that thing didn't hap-
pen}?

After showing that this method tracks neg-raising judgments reported in
the literature well (their Appendix C), An & White apply their method to all
English verbs acceptable with a declarative complement under White & Rawl-
is' (2018) declarative-taking criterion, varying both the subject (\textit{first} v. \textit{third})
and tense (\textit{past} v. \textit{present}).\textsuperscript{7} The subject-tense variants for the item in (11) are
exemplified in (12).

(12) \{I \{didn't, don't\}, A particular person \{didn't, doesn't\}\} think that a
particular thing happened.

\textsuperscript{7} An & White additionally follow White \textit{et al.} (2018) in collecting similar judgments for predi-
cates that take infinitival complements. Since Theiler, Roelofsen & Aloni only focus on finite
interrogatives — and thus it is unclear how to correctly test \( NR \) for infinitival-taking predi-
cates — I focus only on finite declaratives.
To obtain a measure of each predicate’s neg-raising with each combination of person and tense from responses to prompts such as (11), White & Rawlins (2018b) apply a mixed model-based normalization procedure (see An & White 2020: Appendix D). To obtain a single measure of neg-raising for each predicate, I take the maximum of these normalized neg-raising judgments across all four subject and tense variants for a particular predicate, with the assumption that a predicate is neg-raising if it is neg-raising with at least one combination of subject and tense.

Figure 3 (right) plots White & Rawlins’ (2018) measure of responsivity against this measure of neg-raising, with transparency corresponding to the declarative-taking weight. The line shows a linear regression weighted by declarative-taking weight. The corresponding correlation weighted by declarative-taking is 0.22 (95% CI = [0.14, 0.30]). This correlation violates the predictions of NR, even under the worst-case simulation assumptions discussed above, suggesting that NR is false as a generalization about the lexicon as a whole.

4 Corpus evidence against the generalizations

Having established that at least V and NR fail when applied to the lexicon as a whole, I now address the possibility that they might be rescued by constraining their statement further—e.g. in the way V + P is constrained to preferential predicates. Such a constraint might serve to exclude peripheral classes of predicates, while retaining the core contrast in (1). On the basis of corpus examples, I argue that even this core contrast cannot be retained and that all three generalizations should be jettisoned.

I select examples from two corpora: the Corpus of Contemporary American English (COCA; Davies 2008) and the iWeb Corpus (Davies 2018). COCA is a corpus that, at the time of my search, contains over 500 million words spread over five genres: spoken, fiction, popular magazines, newspapers, and academic texts; and iWeb is a corpus containing over 14 billion words of web text (blogs, news articles, etc.). To search for examples, I use each corpus' web interface to query for think, believe, hope, and fear in any morphological form, followed by whether—e.g. for think: [THINK] [WHETHER].

I focus on polar (whether) interrogatives because, following Egré, I assume that polar interrogative selection is more constrained than constituent interrogative selection.
On believing and hoping whether

the results of this search, I select examples that I (a native speaker of English acquired in Southern California) take to be perfectly acceptable in context.9

I break discussion of these examples into two sections based on which generalizations they are relevant to. In Section 4.1, I discuss think and believe, showing that neither V nor NR can explain these examples. I then turn in Section 4.2 to hope and fear, showing that V + P cannot explain these examples.

4.1 Thinking and believing whether

As discussed in Section 2, both V and NR predict that think and believe should not take interrogative complements. But think is attested with interrogative complements in transcribed speech (13), periodical text (14), and internet text (15).

(13) a. The image of having the members of one branch of government standing up[...]cheering and hollering while the court[...]has to sit there, expressionless[...]is very troubling. And it does cause you to think whether or not it makes sense for us to be there.
   b. [...]the righteousness is unbelievable and people[...]will have to think whether they want four more years of that.

(14) a. When Jan Brown completed her safety briefing for the passengers, she tried to think whether she had covered everything.
   b. I'm trying to think whether I'd have been a star today or not.

(15) a. [O]ften, when listening to some other players (especially beginners) I start to think whether there's an unwritten law for guitarists to never play an interval bigger than the major third.
   b. [...]he wanted a domain that was memorable, brandable, keyword-rich, and relatively short. That’s tough and he started to think whether it was worthwhile to look into other TLDs.

In at least a subset of these examples, one might attempt to save V by arguing that think is in fact veridical in these contexts (see Spector & Egré’s 2015 approach to predicates like tell). For example, think in (14a) might be paraphrased using remember, and think in (14b) might be paraphrased using

---

9 An anonymous reviewer reports that they find most of the examples cited below acceptable, but that others are not as good for them. An exploration of such idiolectal variation in this area would be interesting, but it is out of scope for the current paper.
figure out, both of which are veridical and non-neg-raising. But with respect to veridicality, this move is somewhat suspect for (13) and (15), wherein reasonable paraphrases seem to involve the predicate consider. Now, consider that may well have a veridical sense — roughly, consider the fact, in contrast to consider the possibility — but that sense does not appear to be the one active in at least (13b), wherein the speaker seems to be encouraging consideration of a possible desire.

These examples may be less problematic for NR, since proponents might argue that think is not neg-raising in (13)–(15) — similar to how believe is not neg-raising in (6), discussed in Section 2 and duplicated below. Remember that Theiler, Roelofsen & Aloni argue that the compatibility of believe with an interrogative complement is only possible because no neg-raising inference is triggered in (6), evidenced by the fact that strong NPIs are not licensed in the complement.

(6) You won’t believe who called (*in ages)!

Before moving forward, I would like to take a brief aside to patch up what I take to be a flaw in Theiler, Roelofsen & Aloni’s argument: neg-raising never occurs with interrogative complements, so it is unclear why one should expect it to occur here. A proponent of NR might argue that this data point is another piece of evidence in their favor. But if this data point is indeed evidence for the generalization, it is quite weak, because it does not dissociate a predicate’s propensity to license neg-raising in a particular context from other syntactic and semantic factors that might block the inference, such as the form of the complement.

With this in mind, I propose that a better test is to minimally modify sentences like (6) to remove any effect of the form of the complement while retaining all other aspects of the context — e.g. by simply converting an interrogative, as in (6), to a declarative, as in (16). When we do this for (6), we get a result consistent with Theiler, Roelofsen & Aloni’s argument: (16) is bad.

(16) *You won’t believe that someone called in ages!

I refer to this as the interrogative-to-declarative test. Applying this test to corpus examples like (17) yields contexts where both think whether and neg-
On believing and hoping whether raising *think* are possible: the strong NPI *until*... is fine in (18) with low attachment to *help*.\(^{10}\)

(17) I was **thinking whether** there was a way to [...] help more than one person.

(18) I wasn’t thinking there was a way to help more than one person (at a time) until Jo got back from lunch.

This form of argument is weak, since the *think* in (17) still might be a different *think* from the one in (18), though such a polysemy is otherwise unmotivated. To posit a regular polysemy of this form, it would be necessary to see other predicates showing similar behavior. *Believe* is such a predicate, and it is compatible with interrogative complements — seen in (6) and corroborated by (19).

(19) a. [...] I didn’t believe the Bible growing up, I wasn’t a Christian growing up, I struggled to **believe whether** I could trust the Scriptures[...]

b. We can choose to **believe whether** the word of God is true[...] or not.

c. I am torn between **believing whether** or not Jagex can detect the RSBot client.

But unlike (6), at least some of these examples pass the interrogative-to-declarative test. For instance, in the context of (20a), the strong NPI *either* in (20b) — analogous to (19b) — is clearly good.

(20) a. We can choose not to believe the teachings of the Buddha are true.

b. We can choose not to believe the word of God is true either.

One property that all of the sentences in (19) share is that, in context, they apparently either do not trigger an *opinionatedness inference* — i.e. the inference that a speaker who uses *NP believe S* endorses \([NP] \text{BELIEVE } \lnot [S] \lor [NP] \text{BELIEVE } [S] \ (\text{Bartsch 1973})\) — or they only do so vacuously: in (19a), an explicit belief is stated about the trustworthiness of the Bible before the use of **believe whether**, assymmetrically entailing the inference; in (19b), a choice

\(^{10}\) For those having difficulty obtaining the low attachment reading, consider a context wherein the speaker’s manager is questioning why they, as team leader at a help desk, were serving only one customer at a time, when the help desk was staffed with three people.
of belief has apparently not been made and thus the speaker's cohort is presumably not yet opinionated; and in (19c), in being torn, the speaker explicitly states that they do not have a firm belief. The opinionatedness inference is implicated in the derivation of the neg-raising inference in some approaches, so this fact could then be used to save \( \text{NR} \) by denying that the conditions for neg-raising are met in context. But beyond substantially weakening the predictive power of that generalization, this move is not possible for all sentences.

Consider (21).

(21) [...]Richard Stavin, a former veteran federal prosecutor [...] declared [...] "[...] I believe it was an organized, orchestrated effort on the part of certain individuals within Washington, D.C. to keep a hands-off policy towards MCA [...]" Believing whether certain individuals within Washington D.C. had an MCA policy is not the same as proving there was such a policy.

Here, the author takes as common ground that Stavin has an opinion, then asserts that having said opinion is not the same as proving that opinion to be true. Beyond being problematic for \( \text{NR} \), this example is also problematic for \( \text{V} \): the content of (21) draws a contrast between the nonveridicality of belief and the veridicality of proof, and so it would be contradictory to interpret believe as veridical in this context.

On the basis of these examples, attesting that think and believe do indeed take interrogative complements, I argue that both \( \text{V} \) and \( \text{NR} \) should be jettisoned.

### 4.2 Hoping and fearing whether

\( \text{V} + \text{P} \) predicts that hope and fear should not take interrogative complements. Indeed, hope and fear are two of the central cases discussed as evidence for \( \text{V} + \text{P} \) by Uegaki & Sudo. But hope is attested with interrogative complements in both speech transcripts (22) and internet text (23).

(22) This Trump/Carson boom really has people like Bush, Walker, Rubio, and others wondering and hoping whether history will repeat itself and whether Republicans will return back to focusing on the establishment choices but it’s all about outsider candidates right now.
On believing and hoping whether

(23)  
  a. I was hoping whether you are able to guide me[...]
  b. I have done a quite a bit of research on using a Limited Co but was hoping whether someone with more experience could confirm my understanding of a few points[...]

A potential worry with at least the sentences in (23) is that they seem paraphrasable using hope that — evoking Karttunen’s (1977) observation that declarative and polar interrogative complements appear interchangeable for responsives like doubt.

(24) Jo doubts that Bo left. ≈ Jo doubts whether Bo left.

While such a paraphrase may be available, this availability cannot imply that the interrogative is somehow different from the one found under other predicates: note that, in (22), hope is coordinated with wonder, which is unambiguously interrogative-taking. Thus, even if one argues that hope that and hope whether are in some sense interchangeable, this explanation cannot presume that the interchangeability is due to the interrogative embedded under hope having a distinct semantics.

Similar examples can be found for fear.

(25)  
  a. Interstellar space is so vast that there is no need to fear whether stars in the Andromeda galaxy will accidentally slam into the Sun.
  b. I fear whether this test would run safely on the oxygen sensor as it has a lot of drawback when compared with the others.
  c. [...] I fear whether I’ll have use of my arms/hands by age 55 or 60.
  d. I know parents who seriously fear whether their children will ever hold a meaningful job.

Example (25a) might be explained under Mayr’s (2018) proposal that interrogative embedding for some predicates, like be certain, is licensed by downward-entailing contexts, since the no scoping over fear in (25a) creates such a context. But this move is not available for at least (25b)-(25d), where no downward-entailing operators outscope fear. Further, running the interrogative-to-declarative test on these cases does not yield veridicality inferences about the content of fear’s complement, suggesting that veridicality is not licensing these cases: from (26a), one does not infer that the test would (not) run safely; from (26b), one does not infer that the speaker will not (or
will) have use of their arms/hands; and from (26c), one does not infer that the parents’ children will (not) ever hold a meaningful job.

(26) a. I fear that this test would run safely on the oxygen sensor as it has a lot of drawback when compared with the others.
   b. [...]I fear that I won’t have use of my arms/hands by age 55 or 60.
   c. I know parents who seriously fear that their children will ever hold a meaningful job.

On the basis of these examples, attesting that hope and fear do indeed take interrogative complements, I argue that V + P should be jettisoned.

5 Conclusion

The proposals discussed here pursue the laudable goal of associating selection with independently motivated lexical properties, such as veridicality, neg-raising, and preferentiality. This means that the generalizations on which these proposals rest are predictive and thus falsifiable. I have presented evidence from both large-scale experimental data and examples attested in corpora that these generalizations are, if not outright falsified, so frail that they should be jettisoned.

Importantly, though, this finding does not imply that theories of clause selection stated in terms of lexical semantic properties should be abandoned wholesale. It remains a live possibility that some alternative set of lexical properties might be found that predict clause-selection—e.g. event structural properties, such as stativity, durativity, and telicity (White & Rawlins 2018a; see also Kratzer 2006, Moulton 2009, Bogal-Allbritten 2016).
